BITCOIN VS GOLD: MONTHLY CORRELATION ANALYSIS 2020–2025

Abstract

In this study, we test if the monthly log-returns of gold and Bitcoin have correlated from January 2020 to July 2025. Using raw gold prices from "Gold Price" data from datahub.io, which aggregates monthly prices from historical data published by the World Gold Council and licensed under Public Domain Dedication & License (PDDL), datahub.io, combined with Bitcoin data from the free open source data set published by Mouad Jaouhari from GitHub (licensed MIT), we form a month-end series to compute log-returns. Pearson's correlation coefficient (linear association measure between two continuous data sets) & Spearman's Correlation Coefficient (monotonicity measure) have been computed. In order to augment these results & check if these results prove true irrespective of market conditions & data quality changes over time, we have accomplished Fisher r-to-z conversion & computed "rolling" correlation (r calculated over a "window" w = number of months; example w = 6/12). The Pearson Correlation for full-period data comes out to be -0.069, 95% CI (-0.306;0.176), n=66 months, not supporting reliably. The results were also "rolling" between extreme values (-0.91 & 0.90 over 6 months), & were negative in about 60% of values considered. Further "sub-period" wise results have shown changes in market conditions; results went positive from 2022 & 2023. Channel checks like Spearman Test & Jackknife Tests have freed these results from "outliers" & shown consistency according to market changes. Further results do not say "digital gold" theory.

I. Introduction

The common hypothesis that ‘Bitcoin is digital gold’ means that its returns ought to walk together, particularly during stressed markets. While it is important to recognize that both are stores of value, it does seem very unlikely that they are so intertwined as to walk together, particularly where cryptocurrency or Bitcoin is concerned, as its very nature is speculative. Most research into this topic has covered shorter durations or concerned prices rather than returns, where correlations can often prove spurious. This research proposes to investigate its data on the logarithmic returns for Gold and for Bitcoin for the period 2020 to 2025 to cover COVID-19, various cycles within cryptocurrencies, and broader global shifts.

II. Related Work

However, the “digital gold” story also has been challenged by previous empirical studies. Baur & Hoang (2021) investigate the correlation between Bitcoin and gold for various sample periods and horizons. They find that the correlation of return is in general low, unstable, and in some cases closer to zero. This indicates that the behavior of Bitcoin is not simply that of a competitor for gold. This report continues in the same line of research, but on an introductory

level. It uses the log return on a monthly basis from 2020 to 2025 to check if the behavior of Bitcoin in the past years corresponds to the previous study's findings.

III. Data & Preparation

Data Source.

- **Gold :** The raw dataset "Gold Prices" from DataHub provides monthly gold prices in US dollars dating back to 1833. It is derived from World Gold Council data compiled by Timothy Green and is released under the Open Data Commons Public Domain Dedication and License (PDDL)
- **Bitcoin :** We use the open-source "bitcoin-hourly-ohclv-dataset" (MIT licence) by Mouad Jaouhari on GitHub (epoch timestamps and OHLC volumes).
- Both sources are used solely for education analysis.

Cleaning steps.

- **Gold :** Parsed Date variables are converted to timestamps and Price to numbers. Duplicate observations for each month are treated using last observation carry forward, and observations ≤ 0 are deleted. Dates are indexed to EOM indicators. Filter variable range was from January 2020 to July 2025, resulting in 67 observations.
- **Bitcoin :** Converted TIME_UNIX to datetimes in UTC, auto-detected whether they are in milliseconds or second resolution, dropped the commmas and money signs from the data in column CLOSE_PRICE, eliminated data that was non-positive, eliminated duplicate timestamps by selecting only the last tick per hour, limited data to 2020-2025, and resampled data to End-Of-Month-close using resample("M").last().
- **Merge :** The cleaned data for gold and BTC on the End-of-month (EOM) index was merged using inner join, giving a total of 66 observations from 2020-01 to 2025-07.
- **Returns :** Calculated log-returns: $\Delta \ln P_t = \ln P_t - \ln P_{t-1}$. The first data point for each series has been eliminated.

Reproducibility note.

- All codes, notebooks, and results are managed through the public GitHub repository at: https://github.com/novenoandrewm/BTC-Gold-Correlation. To replicate: clone the repo, create a virtual environment, run `pip install -r environment/requirements.txt`, then run notebooks 01 -10 from the repo's root dir. Outputs will be placed in data/interim/, data/processed/, reports/figures/, and reports/tables/. To generate the same numbers when doing bootstrap estimates, the random seed will be 42 and the same EOM calendar alignment.
- The final sub-period runs from January 2024 to July 2025, because gold data are only available up to July 2025.

IV. Methods

We analyse the co-movement using several complementary techniques :

1. **Full-period correlation :** Analyzing monthly log-returns using Pearson's r (two-tailed p-value significance level), followed by Fisher
2. **Rolling correlation :** Sliding window sizes of 6 and 12 months. Calculate mean, min, max, and fraction of negative windows.
3. **Sub-period analysis :** Non-overlapping blocks: 2020–2021, 2022–2023, 2024–2025 (Pearson r and p-value).
4. **Robustness :** Spearman ρ correlation (monotonic relationship), non-parametric CI from bootstrap method, winsorization (1% trimming), and jackknife method (each series' influence assessed through leave-one-out deletion).

V. Results

a. Full-period correlation

Table 1 below shows the full period Pearson correlation between gold and BTC logarithmic returns. With n = 66 observations, r = -0.069, p = 0.584, no linear correlation can be established reliably, and its likely actual effect is no bigger than 0.5% variance explained, since the 95% confidence interval (CI) for r encompasses zero, ranging from -0.306 to 0.176.

Table 1. Full-period Pearson correlation of monthly log-returns (Gold vs BTC)

n_months	pearson_r	p_value	95% CI (lo)	95% CI (hi)
66	-0.0686	0.5841	-0.306	0.176

Method. Pearson's r with Fisher r-to-z confidence interval.

b. Rolling correlations

To investigate time variation, we calculate 6-month and 12-month rolling correlations. Summary statistics are provided in Table 2, while graphs showing dynamics are provided in Figure 1 (Rolling 6M) and Figure 2 (Rolling 12M).

Table 2. Rolling correlation summary

Window	mean r	min r	max r	% negative
6 months	-0.1062	-0.9095	0.8965	59.0 %
12 months	-0.1591	-0.7576	0.5301	61.8 %

Method. Summary over all rolling windows.

The 6M correlation varies between −0.909 (strongly negative) and 0.897 (strongly positive), reversing signs often (negative during late 2021 to early 2022 and again from mid-2024 onwards, and positive during 2022-2023). The averaged value of −0.106 encompasses these variation cycles, more than 59% are negative, there is a slight tendency towards negative correlation, but the sign and magnitude are unstable.

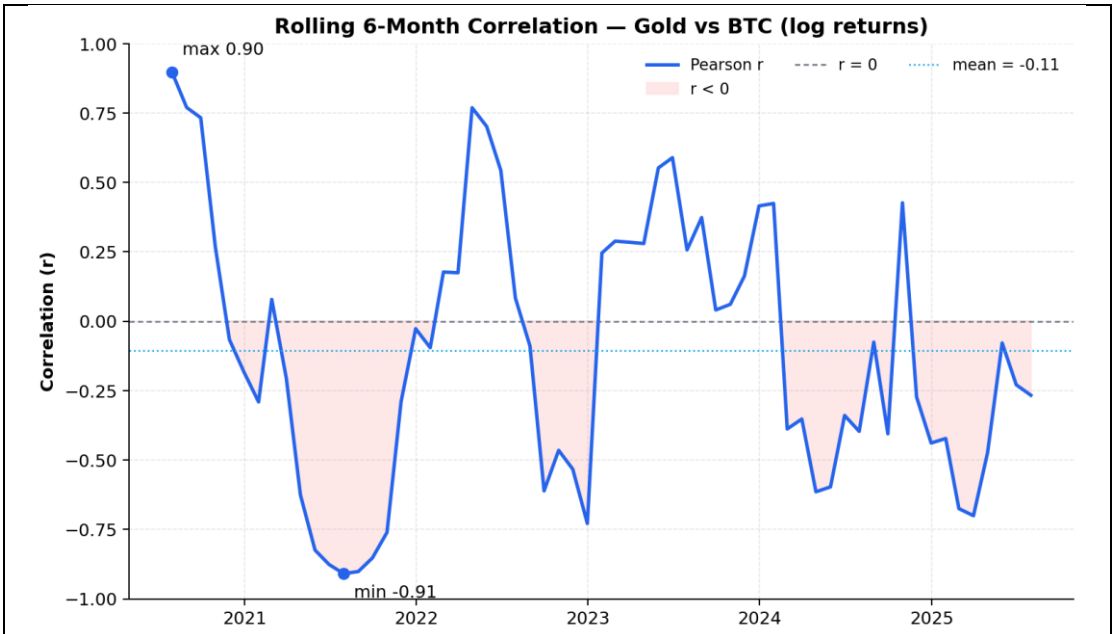

Figure 1. Rolling 6-month correlation (Gold vs BTC).

Method. Pearson r in a 6-month sliding window, EOM timestamps.

For the 12M correlation, signs change while maintaining an averaged value of −0.159 with more than 61% negative.

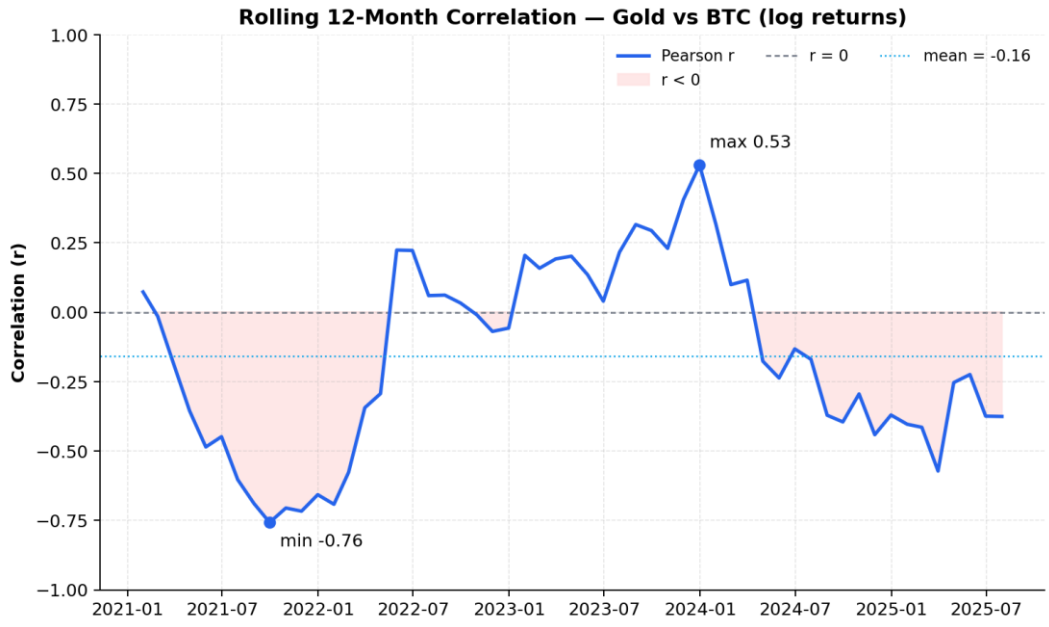

Figure 2. Rolling 12-month correlation (Gold vs BTC).

Method. Same as above, 12-month window.

c. Sub-period correlation

Dividing the data into three parts (Table 3) reveals where the signs of correlation change:

Table 3. Pearson r by sub-period

Period	n	r	p_value
2020-01 → 2021-12	23	-0.2177	0.3184
2022-01 → 2023-12	24	+0.2116	0.3210
2024-01 → 2025-07	19	-0.3618	0.1280

Method. Pearson's r computed within each block.

Gold and BTC correlation was negative in 2020-2021 (not significant), turned positive in 2022-2023, and turned moderately negative again in 2024-2025. The change in signs matches explanations related to global regimes: pandemic driven global liquidity/stimuli, Crypto cycles (bulls and bears), global regimes tighter policies, ETF-driven rallies.

d. Robustness and sensitivity (summary)

In order to gauge the robustness of the findings, a number of sensitivity tests are employed alongside the Pearson correlation coefficient for the full sample. Firstly, the Spearman rank correlation coefficient, which reveals monotonic rather than necessarily linear relationships, is remarkably close in value to the Pearsons coefficient and also

non-significantly different from zero, again suggesting the absence of a strong systematic relationship between the series of monthly returns of gold and Bitcoin.

Second, the bootstrap distribution of the Pearsons coefficient (Figure 3 below) provides a 95% percentile bootstrap confidence interval which encompasses the value of zero, and the value of the coefficient does not change by more than 0.02 when the most extreme 1% of data points in each tail are winsorized in the robustness checks implemented in the notebook. As a third sensitivity test of the findings using the standard Pearson correlation coefficient, the cross-correlation function has been employed to gauge the existence of a lead-lag relationship at various leads and lags from -3 through to +3 months (Figure 4 above).

This revealed only small and non-significant coefficients at each lag interval. Finally, a Jackknife re-estimation of the correlation coefficient (Figure 5 above) makes plain that the deletion of each particular month has yielded a difference of no greater than $|\Delta r| \approx 0.07$ from the value of the reference correlation coefficient. This suggests that no single data point has been particularly important in establishing the sign and size of the correlation coefficient.

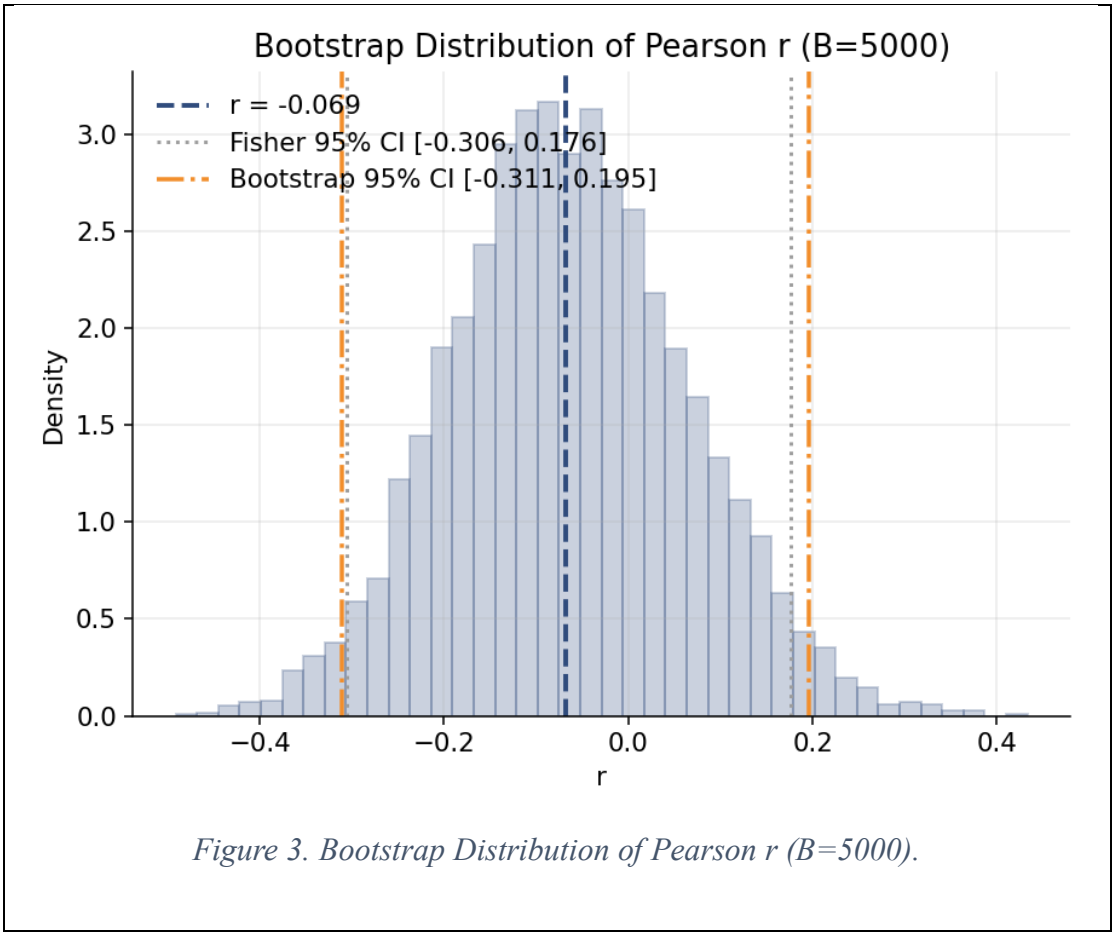

Figure 3. Bootstrap Distribution of Pearson r (B=5000).

Method. Resample the pairs of observations "Gold_ret" and "BTC_ret" of length "n" with replications B = 5000, and compute the value of r using the Pearson method for each replication. Calculate the 95% CI of the percentile endpoints at the 2.5% and the 97.5% level.

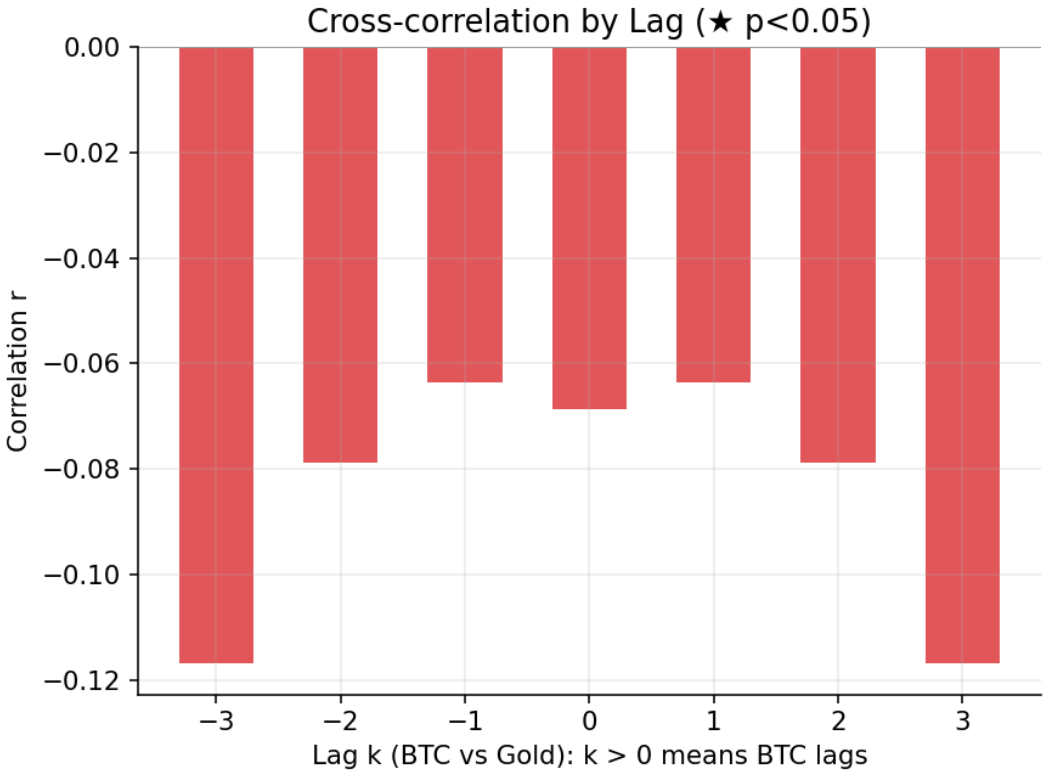

Figure 4. Cross-correlation of monthly log-returns by lag k (BTC vs Gold).

Method. For each k from -3 to + 3, match Gold_ret(t) to BTC_ret(t+k). Rule: if k>0, then BTC follows gold (BTC lags gold and takes k months to react). Compute r and p-value (two-sided) for each k. Indicate ★ if p-value < 0.05.

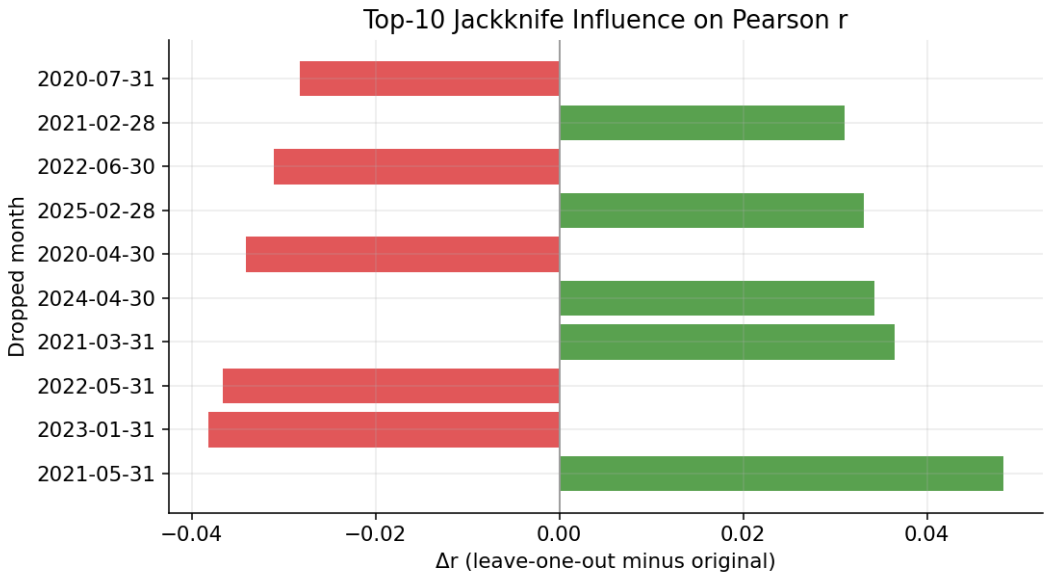

Figure 5. Top-10 Jackknife Influence on r (Δr).

Method. Repeat the estimation by removing one month at a time (leave-one-out). Compute r_without and Δr = r_without − r_full; display the 10 Δr with the largest magnitude.

VI. Discussion

Our findings do not support either a *digital gold* storyline. The full sample Pearson correlation of returns between gold and Bitcoin shows it to be effectively zero and economically small. The rolling sample results draw attention to large swings between large negative correlations in response to crypto crashes (Late 2021 to early 2022, Late 2024 to 2025), but large positive bursts of correlations during relief rallies (2022 to 2023). The results for the subsequent time samples show these pattern changes. The pattern of safe-haven behavior shown by gold contradicts Bitcoin's speculative nature, if crypto crashes occur, strategic investor behavior leads to negative correlations. In contrast, in bull market rallies influenced by liquidity, both may trend upward.

Findings here highlight dependence on the regime; to draw conclusions about co-movements, it's necessary to condition by market context. In single estimation of correlation by analysts or even investors, conclusions may be misrepresented. The results from robustness checks indicate dependence on outliers and thick tails in Bitcoin returns but do not change the conclusion about no fixable correlation.

VII. Limitations and Further Work

Some issues require careful attention. Firstly, the sample of 66 monthly returns is not large; inference may be poor if small effects are present. Secondly, correlation is essentially linear; complex (non-linear) relationships may be overlooked. A different kind of model (perhaps multivariate, possibly 'regime-switching') could be very enlightening. Thirdly, other variables (inflation and possibly interest rates) whose values have been affecting both assets can be downplayed here. These issues would be explored in appropriate models like "DCC-GARCH". Fourthly, monthly returns here finish "End of month."
